Excluded from automatic downgrading and declassification.

All distribution of this report is controlled. Qualified DDC users shall request through Director, Defense Atomic Support Agency, Washington, D.C. 20301

RESTRICTED DATA

This document contains restricted data as defined in the Atomic Energy Act of 1954. Its transmittal or the disclosure of its contents in any manner to an unauthorized person is prohibited.

This document is the author(s) report to the Director, Defense Atomic Support Agency, of the results of experimentation sponsored by that agency during nuclear weapons effects testing. The results and findings in this report are those of the author(s) and not necessarily those of the DOD. Accordingly, reference to this material must credit the author(s). This report is the property of the Department of Defense and, as such, may be reclassified or withdrawn from circulation as appropriate by the Defense Atomic Support Agency.

APPENDIX B

ROCKET VEHICLE PERFORMANCE

B.1 INTRODUCTION

In the determination of a missile's flight path, ground-based instrumentation dispersed over several sites generally allows more flexibility and greater accuracy in data reduction than measuring systems concentrated at a single location. addition to providing less accuracy, single-site systems frequently fail to yield sufficient data for position determination without the introduction of constraints such as parabolic or elliptical motion. To arrive at a trajectory under singlesite conditions, it becomes necessary to assume that the motion of the missile may be characterized by a set of parameters which are functionally related to the measured quantities. A solution is possible if there are at least as many observations as parameters, and if the resulting system of condition equations is sufficiently independent.

The reduction and analysis of a large portion of the observed rocket trajectory data for Projects 6.2, 6.3, and 6.4, was based upon the flight paths

GROUP 1

Excluded from automatic downgrading and declassification

SECRET

of the missiles as a function of time. For many rockets, the various missile tracking systems operating at or near Johnston Island failed to provide adequate coverage to meet all trajectory requirements. Therefore, it became necessary to develop methods of position determination from a combination of various measurements or observations. Frequently, these observations were neither of sufficient quantity nor quality to permit a high order of accuracy. Fortunately, most of the rocket measurements of atmospheric and event parameters could tolerate moderate errors in position determination, provided that the differential in position varied smoothly. In view of the relatively lax requirements for accuracy and the limited precision of the observations, it was considered reasonable to characterize the drag-free portion of the trajectory by simple parabolic motion.

B.2 TRAJECTORY PARAMETERS

With the assumption of parabolic motion within a plane, the reduction problem became twodimensional. If ρ is defined as the horizontal coordinate and y as the vertical, the equations of motion are,

$$\rho = \rho_0 + \dot{\rho}_0(t - t_0) \tag{B.1}$$

$$y = y_0 + \dot{y}_0 (t - t_0) - 1/2 g (t - t_0)^2$$
 (B.2)

where ρ_0 and y_0 are the position coordinates, and $\dot{\rho}_0$ and \dot{y}_0 are the velocity components for the initial time t_0 . The time variable is t, and -g is the vertical component of acceleration resulting from the force of gravity which is assumed constant for each trajectory determination, but variable from rocket to rocket. For convenience, let $T \equiv (t-t_0)$ so that the above equations become

$$\rho = \rho_0 + \dot{\rho}_0 T \tag{B.3}$$

$$y = y_0 + \dot{y}_0 T - 1/2 g T^2$$
 (B.4)

The velocity components are obtained by differentiating the last two equations.

$$\dot{\rho} = \dot{\rho}_{0} \tag{B.5}$$

$$\dot{y} = \dot{y}_{0} - g T \tag{B.6}$$

Hence, if the parameters ρ_0 , y_0 , ρ_0 , and y_0 can be evaluated from the observed data, position and velocity are determined as a function of time by the last four equations.

B.3 TRAJECTORY SOLUTIONS

A complete solution, for the problem as formulated, consisted of using the measured data to evaluate ρ_0 , y_0 , $\dot{\rho}_0$, and \dot{y}_0 , the trajectory parameters. This required the derivation of a system of equations of condition which related the trajectory parameters to the observed data. Since Equations B.3 through B.6 relate the position and velocity components of the missile to the trajectory parameters and time, it is necessary to initially establish a functional relationship between the measured quantitites and the missile's position and velocity. It was sufficient for the rocket flights here discussed to express the slant range r, and the elevation angle ϵ , in terms of the position coordinates, while developing r in terms of both the position coordinates and the velocity components. The equations follow:

$$r = \sqrt{\rho^2 + y^2} \tag{B.7}$$

$$\varepsilon = \tan^{-1}(y/\rho) \tag{B.8}$$

$$\dot{\mathbf{r}} = (\rho \dot{\rho} + y \dot{y})/\mathbf{r} \tag{B.3}$$

Combining the above equations with Equations B.3 through B.6, there result:

$$r = \sqrt{(\rho_0 + \dot{\rho}_0 T)^2 + (y_0 + \dot{y}_0 T - 1/2gT^2)^2}$$
 (B.10)

$$\varepsilon = \tan^{-1}[(y_0 + \dot{y}_0 T - 1/2gT^2)/(\rho_0 + \dot{\rho}_0 T)]$$
 (B.11)

$$\dot{\mathbf{r}} = [(\rho_0 + \dot{\rho}_0 T)(\dot{\rho}_0) + (y_0 + \dot{y}_0 T - 1/2gT^2)(\dot{y}_0 - gT)] \times$$

$$\left[\sqrt{(\rho_{o} + \dot{\rho}_{o}T)^{2} + (y_{o} + \dot{y}_{o}T - 1/2 \text{ gT}^{2})^{2}}\right]^{-1}$$
 (B.12)

In particular, when $t = t_0$ so that T = 0, Equations B.10, B.11, and B.12 reduce to:

$$r_0 = \sqrt{\rho_0^2 + y_0^2}$$
 (B.13)

$$\varepsilon_0 = \tan^{-1}(y_0/\rho_0) \tag{B.14}$$

$$\dot{\mathbf{r}}_{0} = (\rho_{0}\dot{\rho}_{0} + y_{0}\dot{y}_{0})/\mathbf{r}_{0} \tag{B.15}$$

where r_0 , ϵ_0 , and \dot{r}_0 are, respectively, the slant range, the elevation angle, and the component of velocity in the direction of the radius vector at time $t = t_0$. The equations of condition were obtained by substituting measured data in one or more of Equations B.10 through B.15 or in equations derived from various combinations of these. Ιf more than four observations were available, the system would be over-determined, and in general, would require rather extensive computation. selecting a set of equations of condition, caution was required to avoid a system in which the equations were so nearly dependent that they failed to yield a reliable solution. For example, observations of slant range for four times at the same site generally provided a very weak solution. Likewise, poor results were experienced from a set of observations consisting of elevation angle measurements for four times at a single location. However, several combinations of single-site observations provided useful results. Computational methods for three of these will be considered in detail below.

If measurements of either slant range or its first time derivative are available for the major

portion of a missile's trajectory, together with the elevation angle for at least the initial portion of the flight above the effective atmosphere, its trajectory may be determined from measurements of $\mathbf{r}_{_{\mathrm{O}}}\text{, }\dot{\mathbf{r}}_{_{\mathrm{O}}}\text{, and }\boldsymbol{\epsilon}_{_{\mathrm{O}}}$ for time $\boldsymbol{t}_{_{\mathrm{O}}}$ and a slant range, $\boldsymbol{r}_{_{\mathrm{O}}}$ for any time, t, other than t_0 . If only the slant range is measured, r may be obtained by either numerical or graphical differentiation. On the other hand, if r is the measured quantity, integration man be used to derive the necessary values for r. The latter process requires a continuous record of r from launch. Preferably, t_0 should occur on the upward leg of the trajectory and t on the downward leg. Both times are, of course, restricted to that portion of the trajectory where the missile is in free flight and above the effective atmosphere.

With ϵ_0 and r_0 as input, initial position for time t_0 may be readily obtained from the equations,

$$\rho_{0} = r_{0} \cos \epsilon_{0} \tag{B.16}$$

$$y_{0} = r_{0} \sin \epsilon_{0}$$
 (B.17)

Solutions for the remaining trajectory parameters require Equation B.15 which may be written in the form,

$$\dot{\rho}_{o} = (r_{o}\dot{r}_{o} - y_{o}\dot{y}_{o})/\rho_{o}$$
 (B.18)

Substituting for poin Equation B.10, yields,

$$r = \sqrt{[\rho_0 + {(r_0 r_0 - y_0 y_0)/\rho_0}T]^2 + [y_0 + y_0 T - (1/2)gT^2]^2}$$
(B.19)

After squaring and simplifying, this reduces to

$$A\dot{y}_{0}^{2} + B\dot{y}_{0} + C = 0$$
 (B.20)

Where,

$$A = 1 + (y_o/\rho_o)^2$$

$$B = -[(gT + (2r_o\dot{r}_oy_o)/\rho_o^2]]$$

$$C = \{[r_o\dot{r}_o/\rho_o]^2 + [(r_o^2 - r^2)/T^2] + [2r_o\dot{r}_o/T]$$

$$-g[y_o - (gT^2)/4]\}$$

One of the solutions for Equation B.20 yields a false result and may be neglected. The valid solution for \dot{y}_0 is obtained from:

$$\dot{y}_{o} = [-B - \sqrt{B^2 - 4AC}]/2A$$
 (B.21)

 $\dot{\rho}_{_{_{\scriptsize O}}}$ may now be evaluated with Equation B.18 to complete the solution.

If a reliable estimate of \dot{r}_0 is available, the method can be altered slightly to accept as input ϵ_0 , r_0 , and measurements of slant range, r_1 and r_2 , for two times, t_1 and t_2 , such that $t_0 < t_1 < t_2$. If $T_1 \equiv (t_1 - t_0)$ and $T_2 \equiv (t_2 - t_0)$, the equations of condition may be written as

$$[\rho_0 + \rho_0 T_1]^2 + [y_0 + \dot{y}_0 T_1 - (1/2)gT_1^2]^2 = r_1^2$$
 (B.22)

$$[\rho_0 + \dot{\rho}_0 T_2]^2 + [y_0 + \dot{y}_0 T_2 - (1/2)gT_2^2]^2 = r_2^2$$
 (B.23)

Since ρ_o and y_o may be determined by Equations B.16 and B.17, the above system contains the unknowns $\dot{\rho}_o$ and \dot{y}_o . The solution of Equations B.22 and B.23 may be obtained rather quickly by employing an iterative type of computation in which an initial approximation to the result is improved by a series of corrections until the desired number of significant figures is obtained.

A reduction problem, which occurred frequently in the trajectory determinations here discussed, required a trajectory determination from a series of elevation angle measurements recorded as a function of time. However, a system of equations derived

from observations of elevation angle alone is weak and the results unreliable. Fortunately, these reductions were required for rockets that were highly consistent in performance throughout the powered portion of flight. Hence, slant range could be rather accurately related to flight time near burnout. When such an estimate of slant range was combined with three observations of elevation angle, the resulting set of equations provided relatively reliable results.

When elevation angles alone were available, the input for the computation consisted of r_0 , the slant range for time t_0 , and three elevation angles, ϵ_0 , ϵ_1 , and ϵ_2 , corresponding to times t_0 , t_1 , and t_2 . The times were related so that $t_0 < t_1 < t_2$ with t_0 occurring on the upward leg of the trajectory and t_2 on the downward leg if possible. All three times were, of course, selected for a drag-free portion of the trajectory.

Proceeding with the derivations, the assumed value for $r_{_{\hbox{\scriptsize O}}}$ and the observed $\epsilon_{_{\hbox{\scriptsize O}}}$ may be substituted directly into Equations B.16 and B.17 to determine

the position of the rocket at the initial time, t_o . With ρ_o and y_o known, Equations B.22 and B.23 may be solved for the unknowns, $\dot{\rho}_o$ and y_o . The resulting solution consists of

$$\dot{\rho}_{0} = [D(y_{0} + 1/2 gT_{1}T_{2}) + E\rho_{0}]/F$$
 (B.24)

$$\dot{y}_0 = [(\tan \epsilon_2(\rho_0 + \dot{\rho}_0 T_2) - y_0)/T_2] + gT_2/2 \quad (B.25)$$

where,

$$D = (T_2 - T_1)$$

E =
$$(T_1 \tan \epsilon_2 - T_2 \tan \epsilon_1)$$

$$F = T_1 T_2 (\tan \epsilon_1 - \tan \epsilon_2)$$

B.4 RESULTS

The trajectories, which are presented in graphical form in Figures B.1 through B.54, were determined from the best observations available for the particular rocket. Where possible, the computed trajectories were derived from flight paths obtained by missile tracking systems such as radar or the Cubic system. For these flight paths, parabolic trajectories were fitted to the tracking results. In

the absence of data from radar or the Cubic system, flight paths were computed by one of the methods previously described. In general, elevation angle measurements were preferred to observations of slant range for input data; the latter, in turn, were given preference over rate of change in slant range. This order of priority was dictated by the methods of measurement which resulted in better accuracy in the angle measurements than in the observations of slant range. In Figures C.10 through C.34 are plotted the azimuth-elevation data derived from the GMD tracking system and used as the principal source of angle measurements for the trajectory determinations.

The parameters which characterized the motion of each rocket are presented in Table B.l. In addition, the source of the input data for the trajectory determination of each rocket is indicated. Elevation angle input is represented by ϵ and slant range by r. The value for g is an average value based on the apogee of the flight

path. In practice, initial estimates were adjusted by an iterative procedure until the values for g were consistent with the computed trajectory. It should be observed that trajectories for Rockets 8 and 9 were well determined by radar. These trajectories were of sufficient duration that, to obtain a better fit to the observations, ρ was redefined by the equation:

$$\rho = \rho_0 + \rho_0 T + (1/2) \rho_0 T^2$$
 (B.26)

For Rocket 8, $\rho_0 = -0.000546 \text{ km/sec}^2$, and for Rocket 9, $\rho_0 = -0.000478 \text{ km/sec}^2$.

A three-dimensional trajectory may be obtained from the parameters of Table B.1 by adding the following equations to the previous development:

$$x = \rho \cos \alpha \qquad (B.27)$$

$$z = \rho \sin \alpha$$
 (B.28)

where a is the azimuth angle measured clockwise from north. A right-hand coordinate system is formed by x, y, and z, in which y is the vertical, x is positive north, and z is positive to the east.

The origin of the system is located at Point John. The unit of length in the table is the kilometer, and the unit of time is the second. t_0 is the time after launch.

B.5 DISCUSSION

The accuracy of the computed trajectories is primarily a function of the type of input data used to determine the trajectory parameters. The most accurate reductions consist of the results derived from radar and Cubic tracking measurement. Of moderate accuracy are those based on elevation angle measurements. Finally, the reductions of uncertain quality are those derived soley from measurements of slant range.

The predominant error, in the parabolic flight paths fitted to the reductions of radar and Cubic tracking data, entered as a result of assuming parabolic motion. The tracking error of either system is negligible in comparison to the error introduced by the curve-fitting procedure. Hence, the error in the computed trajectory is essentially equivalent to the error in fitting.

Generally, the uncertainty in position for such trajectories varies from 0.5 km on the upward leg of the trajectory to 1.5 km on the downward leg.

In considering the quality of the trajectory determination for other types of input data, direct evaluation of the errors is impossible, since there exists no well-defined trajectory for comparison. However, Table B.2 offers a method for indirectly evaluating the accuracy of those trajectories which were derived from measurements of elevation angles. Presented in Table B.2 are estimates of altitudes at which the rockets began to nose-over upon reentry into the effective atmosphere on the downward leg of the trajectory. This reentry phase is primarily a function of the aerodynamic characteristics of the rocket. entries in Table B.2 were obtained by estimating nose-over times from the occurrence of discontinuities in magnetometer records and also in GMD and AGC field strength measurements. For many rockets, these times could be determined from all three sources with an accuracy of from 1 to 5 seconds. Missile altitudes corresponding to

nose-over times were extracted from the computed trajectories for entry in Table B.2. When more than one measurement of nose-over time was available for a rocket, an average value was used. is observed that the values are quite well clustered for each rocket type. Since for every rocket, the reentering vehicle consists of the payload and last stage, it is reasonable to include the Honest John-Nike and Honest John-Nike-Nike missiles together for comparison. Excellent agreement in nose-over altitude is apparent for both types of rockets regardless of the source of the reduction data. This strongly suggests that the accuracy of the trajectories based solely on elevation angle data is equivalent to that of trajectories derived from radar or Cubic tracking data. However, other error evaluations indicate that the latter may be slightly more accurate. Hence, reasonable estimates of positional error for trajectories determined from observations of elevation angles would vary from 1 to 2 km over the initial portion of the trajectory, to 2 to 3 km near reentry.

Only two nose-over altitudes were available for rockets of the D-4 type. These altitudes were 84.7 km for Rocket 22, and 59.7 km for Rocket 25. These values are not necessarily in poor agreement if it is considered that Rocket 25 was well behaved, whereas the poor performance of Rocket 22 resulted in such erratic motion that the missile very probably did not reenter tail first. The low nose-over altitude for Rocket 25 is quite reasonable, since the reentry vehicle for this rocket had no tail fins.

It is difficult to estimate errors for reductions derived from range-only measurements. Huge errors could result from a shift in the frequency of the transmitter. If such a shift were abrupt, it could be observed and corrected. However, no satisfactory method was available for the detection of gradual shifts in the transmitter frequency. A reasonable estimate of positional error in such reductions would be 1 to 5 km on the upward leg of the trajectory growing to 5 to 15 km near reentry.

Rocket 19 required special attention. The only observation available consisted of a recording of doppler frequency as a function of time. This record was known to be of poor quality as a result of frequency drift. In measuring nose-over altitudes, it was observed that Rocket 19 turned over at 345 seconds after launch, whereas Rocket 26 nosed over at 346 seconds. These rockets were identical and were programmed to fly identical trajectories. The flight path for Rocket 26 was well determined by radar tracking. Therefore, it was concluded that the best estimate for the trajectory of Rocket 19 could be obtained by using the results for Rocket 26, shifted to the appropriate azimuth for Rocket 19.

In conclusion, positional errors probably vary from 0.5 to 1.5 km for Rockets 8, 9, 11, 15, 17, 19, 20, 24, 26, 27, 28, and 29; from 1 to 3 km for Rockets 2, 4, 6, 7, 10, 12, 13, 14, 18, 21, 23, and 25; and from 1 to 15 km for Rockets 1, 5, and 22.

APPENDIX C

PROPAGATION EXPERIMENT: INSTRUMENTATION AND PERFORMANCE

C.1 GROUND INSTRUMENTATION AND PERFORMANCE

C.1.1 Three-Frequency Experiment Ground Instru-

mentation. The ground receiving antennas for reception of signals at 37, 148, and 888 Mc are shown in Figures C.1, C.2, and C.3, respectively. The performance of these antennas was satisfactory regarding their basic physical and electrical properties; however, because of their fixed beam orientation, they were often receiving signals considerably off from their main lobe axis, with attendant reduction in gain and highly elliptical polarization. There is also a possibility that their beam patterns were significantly distorted because of their close proximity to each other and to adjacent reflecting objects such as metal masts, trailers, and overhead power lines and transformers. Since the three-frequency experiment is basically a differential measurement of the carrier frequency signal phase, any differential distortion of the radiation phase patterns of the ground antennas as a function of angle to reception can introduce errors. The characteristics of

the ground antennas are summarized in Table C.1

The helix lengths were shortened for Blue Gill and King Fish events. This was done to broaden the antenna pattern for improved reception off axis of the helix in the event that the rocket flight direction differed appreciably from predicted, as was the case for Star Fish. An additional set of 148-Mc helixes was installed for Blue Gill and King Fish to cover the large differences in launch angles of the rockets carrying the three-frequency experiment. The proper antennas were connected to the receivers by means of remotely controlled coaxial relays. 888-Mc antennas were put on mounts remotely controlled in azimuth and elevation for proper orientation to cover the different rocket flight directions.

The ground antennas were designed and tested by BRL and built by the General Development Corporation, Elkton, Maryland.

Preamplifiers were placed at each antenna to provide sufficient gain to overcome the loss in the long feed cables to the receivers and give maximum

signal-to-noise performance. The 37- and 148-Mc preamplifiers, designed and built at BRL (Reference 69), had 40-db gain and a 3 to 4 noise figure. The 888-Mc preamplifiers, supplied by the Applied Research Corporation, had 30-db gain and a 7- to 8-db noise figure.

The receivers were of the triple conversion superheterodyne type with the original design providing for all of the local oscillator signals to be derived from one frequency standard to provide phase-coherent doppler data at the three frequencies. However, the synthesizer which provided the nine harmonically related frequencies was found to have excessive phase jitter on the highest local oscillator frequency for the 148- and 888-Mc receivers. A last-minute change in the design was made at Johnston Island using separate local oscillator frequency sources which cured the phase jitter problem but left the 37- and 148-Mc doppler outputs noncoherent, i.e., the dispersive doppler data had to be corrected for local oscillator frequency drift. The receivers were used in this manner for Star Fish-for later events additional

design changes were made which cured the phase jitter problem and restored the phase-coherent doppler outputs. Considerable difficulty was experienced with birdies (spurious signals) in the 888-Mc receiver output, which was serious because of the possibility of locking the tracking filter on to a false signal. The trouble was minimized by separation of common power supplies from local oscillator signal sources. The commercial 888-Mc receivers were very unstable, requiring frequent adjustment of the input RF stages and the automatic gain control (AGC) dc amplifier stages.

Electronic, phase-locked tracking filters
(Reference 30) were used at the last intermediate frequency (IF) output of each receiver channel.
These frequencies were 4, 16, and 96 kc at 37, 148, and 888 Mc, respectively. These were very narrow bandpass filters whose center frequency tracked the input frequency. This was accomplished automatically by the use of a phase-locked, servocontrolled circuit. A large signal-to-noise improvement in the output as compared to the input was obtained. Bandwidths of 25, 50, and 100 cps

were used at 37, 148, and 888 Mc, respectively, during the burning phases of the rockets. Reduced bandwidths were used thereafter for maximum signal-to-noise improvement. Another feature of the tracking filters was their constant-amplitude out-put which was necessary for the doppler adding and differential mixing circuits. The filter enabled tracking of signals which were less than the noise at the receiver output. The tracking filters were models IV and VIII, Interstate Engineering Corporation, Anahiem, California, and Model 207, Electrac Corporation, Anahiem, California.

The outputs of the tracking filters on the 37-, 148-, and 888-Mc channels were the respective biased doppler frequencies. In order to remove rocket spin and faraday effects, the biased doppler from 37-Mc right- and left-hand circularly polarized channels were added and doubled, giving 8 kc plus twice the 37-Mc doppler frequency. Similarly, the biased doppler from the 148-Mc oppositely polarized channels was divided by four, added, then divided by two, giving 8 kc plus one-half the 148-Mc doppler frequency. The 37- and 148-Mc added outputs

were combined in a differential mixer giving the desired dispersive doppler data, i.e., one-half the doppler at 148 Mc minus 2 times the doppler at 37 Mc.

A similar mixing process was used between the 148- and 888-Mc received signals giving the desired dispersive doppler data.

Faraday rotation data was obtained by the procedure outlined below.

If the right hand (RH) and left hand (LH) 37-Mc tracking filter outputs are differenced, the resulting electrical signal contains information given by the expression;

$$(f_f + f_d + f_s) - (f_d - f_f - f_s) = 2(f_f + f_s)_{37}$$
 (C.1)

where, f_f is the faraday rotation frequency, f_d is true doppler frequency, and f_s is the rocket spin frequency. In a similar fashion, differencing RH and LH 148-Mc tracking filter outputs gives

$$2(f_f + f_s)_{148}$$
 (C.2)

Differencing Equations C.1 and C.2 gives,

$$2(f_f+f_s)_{148} - 2(f_f+f_s)_{37}$$
 (C.3)

However, $(f_s)_{148} = (f_s)_{37}$ (spin effect is independent of frequency), so that the expression may be rewritten,

$$(f_f)_{148} - (f_f)_{37}$$

It follows then, the differencing operation represented by the expression C.3 furnishes the difference in faraday rotation rates at 148 and 37 Mc. A similar mixing process was used to obtain the difference in faraday rotation between 888 and 148 Mc. A block diagram of the complete mixing system is shown in Figure 5.7.

The complete data-handling system was conceived, designed, and built at BRL.

A combination of paper chart and magnetic tape recorders was used for data recording.

Receiver AGC, spin, faraday, and dispersive doppler data were recorded on two 8-channel Brush recorders, one in each receiver trailer. Four

Ampex FR 114 tape recorders were used, employing 2000-foot reels of tape run at 60 inches per second to record the biased dippler frequencies which were as high as 110 kc on the 888-Mc channel.

The received signal strengths were recorded for the following frequencies: 36.44, 36.94, 145.76, 147.76, 874.56, and 886.56 Mc. Paper chart recorders were used to record the AGC voltages from the receivers and tracking filters. Chart deflection was calibrated against input signal to the receiver preamplifier in decibels below 1 milliwatt (dbm). The calibration signal was fed out to the preamplifier in the antenna field through a coaxial cable whose attenuation was measured and accounted for in calibrating the chart recorder. A remotely controlled coaxial relay was used to disconnect the antenna and connect the calibrate cable to the preamplifier input. The remotely controlled relay permitted quick checks of the calibration just prior to and following the rocket flights, to minimize errors due to

receiver drift. Calibration signals were obtained from an HP 608D signal generator for the 37- and 147-Mc signals, and from a special crystal-controlled generator for 888 Mc.

The basic source of standard frequencies was a radio-frequency oscillator, Borg Corporation Type 0-471 (XN-1)/U, which produced frequencies of 100 kc, 1 Mc, and 5 Mc with an accuracy of 2 parts in 10⁸. Since frequencies other than the basic 100 kc from the Borg standard were required in various parts of the instrumentation system, both divider and multiplier circuits were used to cover the necessary range.

The Electronic Engineering Company's time code generator, Model ZA-1935, produced outputs of 10 kc and 1 cps CW or pulsed, as well as 1 pulse/minute and 1 pulse/10 minutes, all derived from the 100 kc of the Borg standard. In addition, the unit generated a time code suitable for recording on magnetic tape and displayed this time code on decimal indicators of hours, minutes, and seconds. These were set to correspond with

Universal Time received from WWVH.

There are two major functions performed by the station timing system: (1) synchronized control of data recording equipment, and (2) indication of time on the recorded outputs. Pulse shapers and inverters produced the desired polarity, duration, and amplitude of signals for the timing applications.

An analysis of the 888-Mc channel performance disclosed several factors that caused the noisy signals and short records. The 888-Mc channel was originally designed for a 500-mw transmitter, but the contractor could not meet the 500-mw output specification in the time allotted, and instead delivered transmitters which gave between 80- and 150-mw output, thereby introducing a 7-db reduction in the system margin. The wide divergence of rocket flight trajectories from those predicted caused off-beam reception in

the 888-Mc ground helixes which introduced another 3- to 6-db reduction in signal. The local oscillator injection signal for the 888-Mc receiver had phase jitter that caused a 4- to 6-db r action in receiver sensitivity. The 888-Mc rocket antennas had radiation patterns which were quite deeply lobed because of the large dimensions of the rocket compared with the transmitted wavelength and the interfering effects of the many other protruding antennas nearby. The total effect of all of these factors added up to between 20 and 30 db of additional loss when they occurred simultaneously, which would account for the noisy signals and short records observed in many instances.

C.1.2 Satellite Experiment Ground

Instrumentation. The transmissions received on the ground were the 54- and 324- Mc harmonically related CW signals from

the Transit 4A and 4B satellites. Three independent tracking channels were used, two on 54 Mc and one on 324 Mc (Figure 5.8).

On both 54-Mc receiving channels, the antennas used were standard dipoles with half-wavelength elements placed horizontally, one-half wavelength above the ground plane. One of the dipoles was stationary throughout a satellite pass. second dipole was mounted on a pedestal which was motor driven to rotate in azimuth at about 30 rpm during the pass, this rate being large compared to the predicted magnitude of the faraday rotation rate (Figure C.4). The tracking channel associated with the 54-Mc rotating dipole was used primarily to obtain faraday rotation data. The antenna rotation allowed determination of the direction of faraday rotation and enabled more faraday phase and rate fixes than were obtainable with a nonrotating dipole.

Each time the direction of the incoming linearly polarized signal (or major axis of an elliptically polarized signal) became perpendicular to the length of the dipole, there was a minimum in signal strength concurrent with a sudden 180° phase shift.

The antenna pedestal was equipped with a rotary joint to feed the RF signal from the antenna to the preamplifier. In addition, a contact switch on the pedestal closed a few milliseconds for each revolution of the antenna and provided a marker pulse for determination of the antenna orientation and rotation rate.

It had been anticipated that the rotating joint feeding the signal from the rotating dipole to the base might introduce an intolerable amount of noise into the signal. However, it was found that noise introduced had a negligible effect on the remainder of the system. In many cases, the rotating dipole data channel was able to track the satellite over longer periods of time than the fixed dipole channel.

The antenna used for receiving the 324-Mc signal was a right-hand, 8-turn helix (Figure C.5). The first antennas tried were 324-Mc dipoles, but these were unsatisfactory because the satellite

radiated such a small amount of power at this frequency that an antenna with some gain was required. Because of the rotation direction of the component of circular polarization of the radiated signal at the satellite, a right-hand-polarized antenna was needed.

Ţ

Each antenna fed a preamplifier unit situated at the antenna location. These preamplifiers were designed and built at BRL. They had an overall gain of 40 db, a noise figure of 4 db, and a passband of 2 Mc. They exhibited excellent stability and reliability under field conditions over long periods of operation.

The output of the preamplifiers was fed through long coaxial cables into the tracking station where it served as the input to the receivers. In the 54-Mc channels, the Nems-Clarke Model 2501 special-purpose receivers were used directly. These

were designed for the reception of AM and CW signals, tunable over a range of 55 to 260 Mc, and had a noise figure of 6 db maximum at antenna input. They were provided with a 50-ohm antenna input and an additional 50-ohm input to the second RF amplifier, to allow for the injection of a known reference signal for comparison with the received signal.

In the 324-Mc channel, it was necessary to extend the operating range of the Model 2501 receiver. This was accomplished by the addition of a range extender unit, Nems-Clarke Model REU-300B. This unit was designed to operate in a 50-ohm system, had a noise figure of 14 db, and was tunable from 250 to 900 Mc.

A frequency synthesizer manufactured by Rodhe and Schwarz provided the required RF injection frequency into the receiver for the reception of doppler information. The unit produced a continually adjustable frequency over the range of 30 cps to 30 Mc from an internal or external 100-kc source. Besides the adjustable frequency, other outputs provided were 10-kc and 1-kc CW, and 10-kc and 1-kc pulses. During tracking operations, the output frequency remained constant to within ± 1 cps over a 20-minute period of time.

A frequency multiplier was used in conjunction with the synthesizer for frequencies above 30 Mc.

In the case of the 54- and 324-Mc Transit frequencies, the frequency multiplier used the 27-Mc

output of the synthesizer as input to two channels. The first channel simply doubled the frequency to 54 Mc, while the second channel doubled, then tripled, and again doubled the frequency to produce 324 Mc.

The basic function of the tracking filter used (Reference 70) was to provide the detection of doppler signals much weaker than the noise at the output of the receiver. A signal-to-noise improvement between 20 and 30 db was obtained by use of an extremely narrow filter bandwidth relative to the input signal bandwidth.

The outputs of the tracking filters on the 54-Mc and 324-Mc channels were audio-frequencies, and corresponded to the biased doppler frequencies. The 54-Mc doppler was multiplied by six and subtracted from the 324-Mc doppler to obtain the dispersive doppler. The equipment for doing this was the multiplier-mixer unit (References 13 and 14) designed and constructed at the BRL.

The total doppler change during a pass of the Transit satellite was about 2 kc on the 54-Mc carrier and 12 kc on 324-Mc carrier. To accommodate

the same type of tracking filter in each channel, the frequency of the local oscillator was set to provide an output frequency bias on the 54-Mc channel of 2.5 kc at the time when the true doppler frequency was zero. The bias frequency on the 324-Mc channel was then 15 kc. Therefore, during the actual tracking operation, the doppler effect caused the output frequency to vary between 1.5 kc and 3.5 kc on the 54-Mc channel and between 9 kc and 21 kc on the 324-Mc channel. Consequently, the two biased doppler frequencies varied by amounts exceeding one octave, so that conventional frequency multipliers could be used in this application.

The cross polarization nulls due to faraday rotation of the 54-Mc signal received by the rotating dipole antenna were superimposed on the cross polarization nulls due to the antenna rotation. The faraday fading frequency varied from a maximum of about 0.3 cps when the satellite was south of Johnston Island to zero when the satellite was north of the Island. The antenna rotation frequency was about 0.5 cps, giving an antenna fading

rate of 1 cps. Hence, the faraday frequency acted as a small frequency modulation on the antenna rotation carrier. Therefore, the frequency of the resultant signal, as it appeared at the correlation output of the tracking filter, varied between the limits of 0.7 cps to 1.3 cps. During periods of very low signal level, there was also present at the correlation output varying amounts of noise due to phase jitter which was not related to faraday rotation. Since this noise was usually of a frequency high compared with 1 cps, a very low pass filter of 2-cps cutoff was introduced to eliminate it. Using conventional construction, this filter would have been too large to be practical. Therefore, a filter was designed to employ electronic multiplication of reactances, resulting in very satisfactory elimination of the noise. The resultant signal, as it was used with automatic digitization equipment, introduced considerably fewer spurious pulses than did a nonfiltered signal

The information recorded may be summarized as follows: (1) doppler frequency on three data channels, (2) AGC voltage on three data channels,

(3) dispersive doppler, (4) one-pulse-per-second timing, (5) WWVH time, (6) local oscillator frequency, and (7) low pass filtered correlation.

The biased doppler frequency on one 54-Mc data channel and the 324-Mc data channels was also recorded on analog charts of frequency versus time. To accomplish this, the output of the tracking filter was put into a frequency integrator. The dc output of the integrator, being proportional to the input frequency, was recorded on a Varian Associates paper strip chart recorder to give the desired data.

The dispersive doppler frequency was recorded on a paper strip chart recorder along with the timing pulses, the AGC voltages, low pass filtered correlation, and timing pulses. A Brush Instruments Company 8-channel strip chart recorder was used.

It was important to have available on magnetic tape the signals obtained by each receiving channel during the satellite passes. This record served as a backup in case of equipment failure in the system and could be used to recover the original data at a later time. Also, the data on the magnetic tape was later used as input to automatic digitizing

equipment in order to obtain the dispersive doppler and faraday rotation throughout the pass. A magnetic tape recorder, Ampex Model FR-114, was used at the receiving station and at the data-handling station to record and play back the received signals.

After few satellite passes had been made, it became evident that good signals could be obtained on the large majority of passes which were within ± 600 miles of the Johnston Island site. Because part of the tracking equipment was also used for another experiment, it was decided to confine the satellite tracking operations to only those passes that were within the above range. Improved signal on the 324-Mc channel could have been obtained when the satellite was close to the horizon if the antenna could have been operated in a tracking mode. This was confirmed by using an existing high-gain tracking antenna of the Cubic Corporation facility on some selected passes.

The stability of the internal oscillator in the circuit for extending the frequency range of the commercial receiver used at 324 Mc was not completely satisfactory. A long warm-up time

was necessary to insure

adequate signal reception. Installation of a

crystal-controlled local oscillator would elimi
nate this difficulty on any future operations.

In Tables C.2 through C.13 are summarized the kinds of recordings made in the BRL trailers for both the rocket and satellite propagation experiments.

C.1.3 GMD Telemetry and Tracking Ground

<u>Instrumentation.</u> The purpose of using the GMD radiosonde ground set was twofold:

- (1) the GMD served as a backup telemetry system,
- (2) the GMD served as a backup angular tracking system. In the nose cones employed on Nike-Cajun rockets, there was insufficient space for the Cubic Corporation (AME/DME) tracking beacon, and the GMD beacon furnished the only source of tracking information for these vehicles.

The GMD set, originally designed to track a balloon-borne radiosonde transmitter in the 1660-to 1700-Mc frequency range, was modified for rocket tracking. A pictorial view of the tracker is shown in Figure C.6. Figure C.7 shows

the components of the GMD tracking and telemetry system. Three GMD sets were used, identified as sets A, B, and C. The physical location of the three GMD antennas relative to the control block-house (Building 200) and the telemetry vans is shown in Figure C.8. The control and recording instruments inside of the GMD van are shown in Figure C.9. Firing of the rockets automatically initiated a one-second-interval recording of azimuth and elevation data.

Modifications made to the GMD system were:

(1) a series resistor and output shunt capacitor were attached to the receiver AGC in order to record received signal strength, (2) the control recorders were modified to accept a l/sec printing rate, (3) an automatic start relay system was built into each recorder in order that the printer would start as each rocket lifted, (4) tunnel diode RF preamplifiers were used on Rockets 11 through 29, inclusive, with the exception of Rockets 13 and 17. The preamplifiers increased the signal-to-noise ratio of the GMD recievers by a factor of 10 db.

Signal strength recordings were made on Brush type Mark II records. Each receiver AGC was calibrated from -20 to -110 dbm in 2-db steps. Response time tests of the receiver-recorder combination were also made. A signal decrease of 100 db deflected the recorder pen from full scale to zero in 90 msec; an increase of 100 db deflected the pen from zero to full scale in 10 msec.

In order to calibrate the tracking mode of the system, a position and angle survey was made for each GMD set. The position of each set was surveyed with respect to the Johnston Island grid system. The reference used for angle measures was the line from Point Joe to Point John which had a true bearing of 65 degrees, 13 minutes, 19 seconds. In the Johnston Island grid system, the position of each set was as follows: (1) A set, North (N) 199, 670, East (2) 199, 705; (2) B set, N 199, 714, E 199,682; (3) C set, N 199, 660, E 199, 516. The accuracy of the survey was ±1.0 foot.

Azimuth angles of each set were referenced to true north; in order to determine these angles accurately, a reference 1670-Mc beacon was placed

on the northeast corner of the balcony on the airport control tower. The true azimuth angles for each tracker were measured by placing a transit over the reference beacon and measuring the angle between the star Polaris and each GMD set. These measured angles were corrected for a bearing of true north. The elevation angle between the tracker and the reference beacon was also measured with a transit. The accuracy of the measurements was ± one minute of arc. Prior to each series of rocket flights, the sets were locked on the reference beacon signal, and the measured angles were set on the dials of the tracker and control recorder.

In Tables C.14 through C.40 are summarized the GMD telemeter-tracking operations for each rocket of Projects 6.2, 6.3, and 6.4 carrying the GMD beacon. Figures C.10 through C.34 present the GMD azimuth and elevation tracking data.

C.2 ROCKET INSTRUMENTATION AND PERFORMANCE

C.2.1 Three-Frequency Experiment Rocket Instrumentation.

The rocket-borne instrumentation for the threefrequency experiment consisted of a transmitting beacon and associated antennas. A block diagram of the beacon is shown in Figure 5.1, and a photograph in Figure 5.2. The beacon was 5.5 inches in diameter by 5 inches long and weighed 7.7 pounds. The fundamental frequency of 37 Mc was generated by a transistorized, crystal-controlled oscillator. The output of the crystal oscillator was amplified by a transistor amplifier to provide two outputs at 37 Mc. One output was connected to the antenna and provided a signal power of 150 mw. The other output signal was fed to a 4-times frequency multiplier consisting of two cascaded transistor doublers. The 148-Mc output from the multiplier was amplified by a transistor amplifier to a power level of two watts. One hundred fifty mw of this power was diverted to the antenna, and the remainder was fed to a 6-times frequency multiplier. multiplier consisted of a cascaded varactor doubler and tripler giving an output at 888 Mc of 150 mw.

The closely controlled temperature for the crystal oscillator was obtained by using the heat-

of-fusion principle (Reference 70). The crystal was submerged in eutectic alloy, Cerrolow 117, which was partially melted prior to rocket lift-off. The alloy had a melting point of 47°C, which, by the heat-of-fusion principle, provided a constant temperature until all of the alloy was melted. A carefully predetermined amount of alloy was melted prior to launch by an externally controlled heating element to bring the mixture up to a constant temperature and to take care of any heat loss in the early part of the flight. During the preflight thermal preparation, a careful balance was maintained between the amount of solid and melted alloy to insure that at take-off sufficient alloy was melted to furnish heat lost during the first minute of flight, while leaving sufficient reserve of solid material for absorbing heat in the remainder of the flight.

The three-frequency beacon was powered by mercury batteries with voltages of 4, 16, and 60 volts. The 4-volt battery powered the oscillator and had sufficient capacity to operate

it for 500 hours. The oscillator was turned on well in advance of firing to insure stable operation. The 16- and 60-volt batteries could power the beacon for 1 hour.

A Ledex stepping relay was used for turning the beacon on and off remotely. Monitor detectors were used on the 37- and 888-Mc outputs, giving 4 volts at normal output. The dc voltage from these detectors was telemetered via the payload telemetering system. The inside temperature of the beacon can was also telemetered. Only Rockets 11, 12, 14, 17, and 22 showed appreciable changes in any of the telemetered monitors; comments on these changes are given in Tables C.41 through C.58.

Remote indicators in the blockhouse were available for monitoring beacon temperature, oscillator temperature, Ledex relay position, oscillator heater voltage, and battery voltages. A diagram of the beacon control system located at the blockhouse is shown in Figure C.35.

The 37- and 148-Mc portion of the beacon was originally designed at the University of Michigan

under a previous contract with the BRL. Modifications, improvements, fabrication, and testing of the beacons were done by the BRL. The 888-Mc portion of the beacon was designed and built by the Applied Research Corporation, Port Washington, New York, under contract with the BRL.

Preflight tests of the beacons indicated two problem areas: (1) low output power or complete malfunctioning of the 6-times frequency multiplier unit, and (2) malfunctioning of 37-Mc transmitting transistor. The short time available for design and production of the frequency multiplier units forced the selection of a type of circuitry easily produced in quantity; however, the units had poor operating efficiency, low output power, and critical tuning adjustments. These difficulties were somewhat alleviated for the Blue Gill and King Fish firings for which additional frequency multipliers were made, utilizing an improved type of circuitry having a higher output power.

Frequency drifts of 10 to 20 cps during flight were observed in some beacon oscillators,

because crystals were not available with turning points (df/dt = 0) at the melting point of the alloy (47°C). Most of the crystals had turning points between 50° and 60°C. Operation at 47°C in these cases placed the operating point on the steep negative slope of the crystal frequency versus temperature coefficient (10 cps per degree centigrade). The alloy method was very simple and reliable, but securing large quantities of crystals with turning points coincident with the alloy melting point was very expensive.

Sudden, permanent shifts of beacon crystal frequency of 20 to 30 cps were caused by acceleration during rocket burning and after burnout. Most of the frequency shifts occurred at burnout of the second Nike booster (approximately 60 g). The frequency variations, however, did not interfere with the primary purpose of the three-frequency beacon (i.e., electron density measurements) but did interfere with its secondary function of doppler ranging.

Tables C.41 through C.58 present comments on the 37-, 148-, and 888-Mc doppler and signal AGC,

and on the high and low-frequency dispersive doppler. Also given is the quality of the beacon performance, which was monitored in the beacon and telemetered on Channel 12 of the telemeter system (10.5 kc). These telemetered data were: (1) the RF voltage at the 37-Mc output stage, (2) 888-Mc RF voltage at the output of the 6-times frequency multiplier, and (3) temperature of the beacon package. In five rockets where the 37-Mc output power was initially low, the output power at 888 Mc was normal. This was possible because the input signal to the frequency multiplier was taken off ahead of the 37-Mc output stage.

Rocket antenna systems were designed to fit
the 9-inch-base-diameter Honest John-Nike payload housing and the 18-inch-base-diameter Javelin
(more properly, Argo D-4) and Honest John-Nike-Nike
payload housings. One system used loop antennas
at 37 and 148 Mc and swept-back stub antennas at
888 Mc. The other system used shroud antennas
(Reference 71) at 37 and 148 Mc and stub
antennas at d Mc. A fiberglas nose cone was

used over the antennas with each system. The location and types of all rocket antennas used on Projects 6.2, 6.3, and 6.4 are shown in Figures 5.3 and 5.4. These figures show the location of the three-frequency experiment antennas relative to the other antennas on the rockets.

The Honest John-Nike antenna system for Project 6.3, is shown in the photograph, Figure C.36. Trapezoidal-shaped loops formed of 1-inchwide copper strip were used at 37 and 148 Mc. They were mounted mutually perpendicular, to minimize mutual coupling and radiation pattern interference. Basically, the trapezoidal loops were balanced loop antennas resonated with a capacitor at the gap and matched to 50 ohms. The 37-Mc loop was tap fed near the base at the 50-ohm point. The design of these loops was based on the theory that a single-turn balanced loop with a circumference of 0.3 wavelength or less has a radiation pattern that is omnidirectional in the plane of the loop; also, its pattern is independent of the physical shape of

the loop. The pattern is negligibly affected by the presence of a large, long rocket body if the diameter of the rocket is less than one-half wavelength. Radiation patterns of the 37-Mc loop on the Honest John-Nike rocket on Project 6.3 are shown in Figure C.37. The effect on the pattern of the metal rods used with the AFCRL ion trap and impedance probe experiments is also shown in Figure C.37.

The loop used at 148 Mc was fed at the gap through a two-capacitor matching circuit; radiation patterns for the Project 6.3 Honest John-Nike rockets are shown in Figure C.38. The 37-inch metal rods below the 148-Mc loop caused difficulty in obtaining a good radiation pattern off the rocket tail. The rods reflected the signal nose-ward. An acceptable radiation pattern was obtained by aligning the 148-Mc loop parallel to the 10-foot rods and insulating the rods from the rocket body. The 10-foot rods were effectively insulated from each other and the rocket body at 148 Mc by the inductor connected in series with them for matching to the 3- to 12-Mc region for the RF impedance probe experiment.

Two stub antennas, phased 180 degrees, were used at 888 Mc on the Project 6.3 Honest John-Nike rockets. The stubs were mounted diametrically opposite on the metal cylinder housing the three-frequency beacon, and were swept back at an angle of 45 degrees with respect to the missile axis. Figure C.39 shows the radiation pattern of this stub antenna system.

The Javelin and Honest John-Nike-Nike (Project 6.2) antenna system consisted of shroud antennas at 37 and 148 Mc, and stub antennas at 888 Mc (Figure C.40). A metal nose cone was used inside the fiberglas nose cone to serve as a ground plane for the shroud antennas. The 148-Mc antenna system consisted of two shrouds mounted diametrically opposite on the metal nose cone. The shrouds were electrically phased 180 degrees with respect to each other; the radiation pattern is shown in Figure C.41. For the 37-Mc antenna, a single shroud was used, providing a nearly omnidirectional pattern in the plane of the shroud (Figure C.42). Stub antennas were used at 888 Mc, mounted diametrically opposite on the lower portion of the

metal cone (Figure C.40). These stubs were electrically phased 180 degrees with respect to each other; radiation patterns are shown in Figure C.43.

The rockets for Javelin Project 6.4 used the same antennas as described above except that the antennas were mounted at different places on the rocket. Figures C.44 and C.45 show the locations of these antennas. The radiation patterns of the shroud antennas at the new locations remained approximately the same as before. The stub antennas were moved to the upper portion of the metal nose cone, but patterns are not available for this location. The 888-Mc stub antennas were redesigned for the King Fish event to improve the mechanical mounting. The redesigned stub is shown in Figure C.46.

The 37- and 148-Mc loop antennas were designed and built by the BRL. The 37- and 148-Mc shroud antennas were designed at the BRL and built by the General Development Corporation, Elkton, Maryland. The 888-Mc antennas used on the Star Fish and Blue Gill events were designed and built by the Marquardt Corporation, Pomona, California;

those used on King Fish were designed and built by the BRL. All antennas were tested and installed by the BRL.

C.2.2 GMD Rocket Instrumentation. The GMD beacon consisted of a cylindrical container 4 inches long by 4 inches in diameter, with an approximate weight of four pounds. The beacon was packaged in a design compatible with the three vehicle configurations discussed in Section C.2.1. The unit consisted of a modulator amplifier, a transmitter using a 7533 cavity oscillator tube, a silver-zinc 6-volt battery, a power change-over Ledex switch, and a dc-to-dc converter with Zenerregulated voltage output. A circuit diagram of the beacon is shown in Figure C.47. The CW transmitter was capable of being frequency modulated by a composite signal in the standard IRIG subcarrier band. The composite of eight FM modulated data signals was used to FM modulate the transmitter. The RF power output was 1 watt. Three frequencies, 1660, 1670, and 1680 Mc, were used to avoid interference when three rockets were in flight simultaneously.

The beacon unit was capable of power changeover from external to internal source by means
of a 28-volt pulse to a control circuit. Provision was made for battery checking and for
charging through the external connector. The
beacons were designed and built by the Marquardt
Corporation, Pomona, California.

The GMD beacon antenna system consisted of three or four slot antennas and a matching and phasing network. Three slots were used on the 6- and 9-inch-diameter nose cones, and four slots were used on the 18-inch-diameter nose cones. The antenna assembly was matched to the transmitter with a VSWR of 1 to 1.5 or better. The antennas were designed and built by the Marquardt Corporation, Pomona, California. A typical slot antenna is shown in Figure C.48, and antenna locations for the different rocket nose cones used in Projects 6.2, 6.3, and 6.4 are shown in Figures 5.3 and 5.4. Antenna radiation patterns are shown in Figures C.49 and C.50.

C.3 ROCKET DISPERSIVE DOPPLER

C.3.1 Star Fish Event. For the rockets launched in the Star Fish event, lack of coherency in the ground-generated receiver injection frequencies produced an unknown bias frequency on the 37- and 148-Mc dispersive doppler data. The expressions 37- and 148-Mc dispersive doppler and 148- and 888-Mc dispersive doppler designate the dispersive doppler obtained by combining the frequencies indicated. Unfortunately, the bias frequency was not only unknown but changed as a result of slight drifts in the ground-based local oscillator during the course of a rocket flight. The bias frequency was present on the paper analog chart recordings of dispersive doppler from the time the rocket beacons were turned on (usually one minute before rocket lift) until signal was no longer being received. Since the rockets did not enter regions of ionization for 1 to 2 minutes after rocket lift, 2 to 3 minutes of bias were available for study and analysis of frequency and frequency drift. In an attempt to

define and eliminate the bias, a least squares approximation (usually a straight line) of the bias frequencies was made with the constraint that the integral under the least squares curve was equal to the numerically integrated bias frequencies measured. The least squares curve was then extrapolated for the remainder of the rocket flight. Deviations from the extrapolated curve were then taken as true dispersive doppler data. Consequently, no great degree of accuracy can be claimed for the dispersive doppler data thus obtained, but later comparisons with data from other sources indicated strongly that the dispersive doppler results can be accepted with a fair level of confidence.

Plots of the integrated dispersive doppler and dispersive doppler frequencies for the Star Fish event are shown in Figures C.51 through C.56.

Comments on the data for the individual rockets are in the following paragraphs.

The 37- and 148-Mc dispersive doppler data for Rocket 1 (Figure C.51) was obtained from magnetic tape recordings of the doppler signals by appropriately multiplying and differencing digitally the

data in a computer. The rocket entered regions of ionization at 163 seconds after rocket lift, and continuous dispersive doppler data was obtained until 600 seconds after rocket lift, at which time the 37-Mc signal was lost and not recovered for the remainder of the flight. The absolute accuracy of the integrated dispersive doppler may be subject to question because of the long time interval over which the extrapolated least squares bias curve was employed, but it is felt that accuracy within ± 15 percent is maintained at least up through rocket apogee. Because of the poor quality of the 888-Mc doppler, no usable 148- and 888-Mc dispersive doppler was obtained for this rocket.

The 37- and 148-Mc dispersive doppler data for Rocket 4 (Figure C.52) was measured exclusively from the paper analog chart recordings. The rocket entered regions of ionization at 65 seconds after rocket lift, and continuous dispersive doppler data was available until the rocket left the regions of ionization at 222 seconds after rocket lift. Since the dispersive doppler data was complete, the additional constraint that the integrated dispersive

doppler must be zero before the rocket enters and after it leaves ionized regions could be used to define and eliminate the bias. As a result, a reasonably high level of confidence may be placed in the dispersive doppler data. There was no usable 148- and 888-Mc dispersive doppler for this rocket.

The 37- and 148-Mc dispersive doppler measurements for Rocket 5 (Figure C.53) were obtained exclusively from the paper analog chart recordings. The rocket entered regions of ionization at 85 seconds after rocket lift, and dispersive doppler data was available until 230 seconds after rocket lift, at which time the 37-Mc signal became so distorted in phase that measurements were no longer possible. There was no usable 148-Mc and 888-Mc dispersive doppler for this rocket.

The 37- and 148-Mc dispersive doppler measurements for Rocket 7 (Figure C.54) were obtained from the paper analog chart recordings. The rocket entered ionization at 105 seconds after rocket lift, and dispersive doppler data was available until 205 seconds after rocket lift, at which time loss of the 148-Mc signal caused loss of dispersive doppler.

Attempts to recover the 148-Mc doppler from magnetic tape recordings were unsuccessful. Since the least squares bias curve required extrapolation for only 100 seconds, the dispersive doppler data should be reasonably accurate. There was no usable 148- and 888-Mc dispersive doppler for this rocket.

The 37- and 148-Mc dispersive doppler data for Rocket 8 (Figure C.55) was derived from magnetic tape recordings of the doppler signals by appropriately multiplying and differencing digitally the recorded signals in a computer. The rocket entered regions of ionization at 151 seconds after rocket lift, and data was continuous until 245 seconds after rocket lift, at which time the 37-Mc signal became so distorted in phase that further recovery of data was impossible. The dispersive doppler was also measured from the paper analog chart recordings and was in excellent agreement with that from magnetic tape recordings of doppler signals but was of somewhat shorter duration. Measurements of the 148- and 888-Mc dispersive doppler were made, but the data appeared to contain a rocket-spininduced error which could not be successfully isolated.

The 37- and 148-Mc dispersive doppler for Rocket 9 (Figure C.56) was measured from a combination of paper analog chart recordings and magnetic tape records of the doppler signals. The rocket entered regions of ionization at 121 seconds after rocket lift, and data was continuous until 740 seconds after rocket lift, at which time the 37-Mc signal was lost. The accuracy of the data is subject to question because of the long extrapolation time for the least squares bias curve. Excellent 148- and 888-Mc dispersive doppler was available for this rocket from 121 seconds to 240 seconds after rocket lift. The agreement between the 37- and 148-Mc and the 148- and 888-Mc dispersive doppler was extremely good over this time period, which lends confidence to the bias correction used for the 37- and 148-Mc dispersive doppler.

C.3.2 Blue Gill Event. For the Blue Gill series of rockets, the lack of coherency in the ground-generated receiver injection frequencies was eliminated, so that the problem of a bias on the 37- and 148-Mc dispersive doppler no longer existed. For all except one of the rockets for

this series, the 37-Mc signal was blacked out or heavily attenuated for extended time periods. This was expected, and it was hoped to fill in these periods with 148- and 888-Mc dispersive doppler. However, a combination of spin-induced errors and low 888-Mc signal levels defeated, for all practical purposes, any usage of the 148- and 888-Mc dispersive doppler. Plots of the integrated dispersive doppler and dispersive doppler frequencies for the Blue Gill event are shown in Figures C.57 through C.60. Comments on the data for the individual rockets are in the following paragraphs.

at H-zero which occurred 120 seconds after rocket lift and was not reacquired until 220 seconds after rocket lift. The rocket had encountered no ionization before blackout occurred, and the quality of the doppler data was so poor after reacquisition of the 37-Mc signal that no 37- and 148-Mc dispersive doppler was obtained. The 888-Mc signal suffered so much distortion in phase that the 148- and 888-Mc dispersive doppler could not be measured.

For Rocket 12 (Figure C.57), the 37-Mc signal fell below receiver threshold 81 seconds after rocket lift and was reacquired 163 seconds after rocket lift. The rocket entered regions of ionization 60 seconds after rocket lift and left ionization 196 seconds after rocket lift. Excellent 37- and 148-Mc dispersive doppler was obtained from 60 to 81 seconds and from 163 to 196 seconds. The 148- and 888-Mc dispersive doppler data was good and in excellent agreement with the 37- and 148-Mc data from 60 to 81 seconds, at which time the 148-Mc signal became phase distorted to the extent that measurement of dispersive doppler was impossible.

For Rocket 14 (Figure C.58), the 37-Mc signal fell below receiver threshold 79 seconds after rocket lift and was reacquired 230 seconds after rocket lift. The rocket entered regions of ionization 60 seconds after rocket lift and left ionization at 244 seconds. Excellent 37- and 148-Mc dispersive doppler data was obtained from the paper analog chart recording from 60 to 79 seconds and from 230 to 244 seconds. The paper analog chart recording was not made during rocket flight, and the 888-Mc doppler could not be recovered from magnetic tape,

so there was no 148- and 888-Mc dispersive doppler available for this rocket.

For Rocket 15 (Figure C.59), 37- and 148-Mc dispersive doppler data was measured from the paper analog chart recordings. The rocket entered regions of ionization 54 seconds after rocket lift and left ionization at 312 seconds. The dispersive doppler data was continuous over this entire interval and was of excellent quality except for a 10-second period between 85 and 95 seconds. Since the dispersive doppler frequency was very low during this period, it is felt very little error was made in measurement, and the results should carry a high level of confidence. Because of very distorted data, there was no 148- and 888-Mc dispersive doppler for this rocket.

For Rocket 17 (Figure C.60), the 37- and 148-Mc dispersive doppler was measured from the paper analog chart recordings. The rocket entered regions of ionization 67 seconds after rocket lift, and dispersive doppler data was available until 110 seconds, at which time the 37-Mc signal fell below receiver threshold. The 37-Mc signal was reacquired 200

seconds after rocket lift, but at this time the 148-Mc was so badly distorted that no further dispersive doppler was obtained. Phase distortions on the 888-Mc signal prevented the acquisition of any usable 148- and 888-Mc dispersive doppler.

For Rocket 18, indications are that the level of ionization in the regions traversed by this rocket were so low that no measurable dispersive doppler was produced.

C.3.3 King Fish Event. For the King Fish series of rockets, considerably more complete, reliable data was obtained than for the two events discussed earlier. For Rockets 19 and 25, extensive usable 148- and 888-Mc dispersive doppler was measured after some corrections were made for a rocket-spin function error which appeared on the dispersive doppler channel. Plots of the integrated dispersive doppler and dispersive doppler frequencies for the King Fish event are shown in Figures C61 through C.67. Comments on the data for individual rockets are in the following paragraphs.

Rocket 19 (Figures C.61 and C.62) was in the air at time of burst, and all three frequencies blacked out at burst time. The 37-Mc signal was out

for about 41 seconds, the 148-Mc signal was out for about 22.5 seconds, and the 888-Mc signal was out for about 2 seconds. The rocket was not in a region of ionization prior to burst time. 37- and 148-Mc dispersive doppler was excellent in quality after reacquisition of the 37-Mc signal at 161 seconds after rocket lift until the rocket left ionization at 340 seconds. The 148- and 888-Mc dispersive doppler channel for Rocket 19 showed data even prior to the time the rocket entered regions of ionization. After some study, it was discovered that this apparent dispersive doppler frequency was a direct function of the rocket spin rate. Realistic data was obtained from the time the 148-Mc signal recovered at 142.5 seconds after rocket lift until 330 seconds after rocket lift, and a correction was then made to the data based on the rocket spin rate function determined from pre-burst observations. The resulting 148- and 888-Mc dispersive doppler showed excellent agreement with the 37- and 148-Mc dispersive doppler.

For Rocket 22 (Figure C.63), the 37- and 148-Mc dispersive doppler data was measured from the paper analog chart recording. The rocket entered regions

of ionization at 110 seconds after rocket lift, and excellent continuous dispersive doppler data was obtained from that time to 350 seconds after rocket lift. There was no usable 148- and 888-Mc dispersive doppler for this rocket.

Rocket 25 (Figures C.64 and C.65) entered regions of ionization 82 seconds after rocket lift. The 37- and 148-Mc dispersive doppler data was obtained from doppler data digitized from magnetic tape recordings from 82 seconds to 255 seconds after rocket lift, after which time accurate recovery of 37-Mc doppler from magnetic tape was not possible. Even prior to 255 seconds, the 37-Mc doppler was considerably distorted in phase, which could easily result in some errors in the derived dispersive doppler. The confidence level placed on the 37- and 148-Mc dispersive doppler must necessarily be degraded because of the poor quality of the 37-Mc signal. The paper analog chart recording for Rocket 25 yielded 148- and 888-Mc dispersive doppler. As with Rocket 19, the data was biased by a frequency which was a function of the rocket spin rate. The data was corrected for this bias,

and dispersive doppler was thus obtained from 82 seconds after rocket lift to 290 seconds after rocket lift. There is reasonably good agreement between the 37- and 148-Mc and 148- and 888-Mc dispersive doppler, but considerably more confidence should be placed in the 148- and 888-Mc data.

Rocket 27 (Figure C.66) entered regions of ionization at 56 seconds after rocket lift and left ionization at 339 seconds. Good continuous 37-and 148-Mc dispersive doppler data was obtained over this entire interval. The quality of the 148- and 888-Mc dispersive doppler data was questionable, and, in view of complete coverage by 37- and 148-Mc data, no attempts at measuring 148- and 888-Mc dispersive doppler were made.

Rocket 28 (Figure C.67) entered regions of ionization 63 seconds after rocket lift and left ionization approximately 330 seconds after rocket lift. Excellent 37- and 148-Mc dispersive doppler was obtained from 63 to 162 seconds and 295 to 330 seconds except that an uncertainty of one cycle in the integrated dispersive doppler exists over the latter interval. A combination of spin modulation

on the dispersive doppler with intermittent loss of the 148-Mc signal to below-receiver threshold made it impossible to retrieve dispersive doppler data between 162 and 295 seconds. There was no usable 148- and 888-Mc dispersive doppler data for this rocket.

The ionization level in the regions traversed by Rocket 29 was apparently too low to produce any dispersive doppler.

C.4 SIGNAL DURATION AND STRENGTH

- <u>C.4.1 Signal Duration Graphs</u>. The duration of received signals from all rocket-borne transmitters used in Projects 6.2, 6.3, and 6.4 are shown in Figures C.68 through C.95. The minimum useful signal level was taken as that level for each system which would provide readable output data.
- c.4.2 Signal Strength Graphs. Received signal strength recordings versus time were made of all of the three-frequency beacon experiment signals, the VHF telemetry, and the GMD signals. These analog signal strength recordings were read and the data replotted as a function of slant range between the rocket and the launch site. The signal strength measurements are shown in Figures C.96 through C.254. A predicted value of

signal strength versus slant range has been included to permit interpretation of signal changes from causes other than increasing slant range. The system parameters used to prepare the predicted signal strength versus slant range curve for the Star Fish event are given in Table C.59.

The propagation attenuation at 1 km (item 6, Table C.59) was calculated using the equation;

 $A = 37.8 + 20 \log F + 20 \log D$ where, A is the free-space attenuation in db assuming isotropic antennas, F is the frequency in Mc, and D is the distance from transmitter to receiver in miles. The received signal strength in dbm (item 7, Table C.59) was the algebraic sum of items 3, 4, 5 and 6 in Table C.59. To construct the predicted signal strength versus slant range curve, use was made of the relation between attenuation and distance given in Equation C.4 which states that the attenuation increases 20 db for each decade increase in distance. Certain of the telemetry transmitters had 10-watt output; instead of the 2-watt level assumed in Table C.59, which increased the predicted signal levels by 7 db. Also, certain of the rockets used linearly polarized telemetry antennas instead of the circular polarized antennas assumed in Table C.59, which decreased the predicted signal values by 3 db. The

predicted 148- and 888-Mc signal levels for the Blue Gill and King Fish events were reduced 5 db because of the shortened helix antenna length used. Figure C.255 shows the predicted signal levels versus slant range for the three-frequency, VHF TM, and GMD systems used on the Star Fish event. Figure C.256 shows similar information for the Blue Gill and King Fish events.
